Abstract

This paper discusses the relationship between monetary policy and oil prices and, in a broader sense, commodity prices. Firstly, it focuses on describing the relationship between key macroeconomic variables relative to oil prices. Subsequently, it discusses the existence of transmission channels through which monetary policy can be propagated to oil prices. It then provides an insight into the central bank’s forecasting process, both by looking retrospectively at the oil price outlook in the past and by analyzing a transitory and a permanent shock (a rise in the oil price of USD 30/b). The simulated oil price shock is calculated from the average level of Brent crude oil price in the first quarter of 2010, i.e. USD 77/b. Furthermore, we also simulated a transitory and permanent slump in the oil price by 20% from the average level of Brent crude oil price in the third quarter of 2014, i.e. USD 100/b.

Key words: Oil price, monetary policy, real interest rate, oil price shock.

1. Introduction

The current debate among central banks is increasingly focused on the role of asset prices in the process of monetary policy decision-making and maintaining of financial stability. However, most small open economies have their attention fixed not only on financial market developments (stock and bond prices and exchange rates) and property prices, but also on commodity prices, in particular the prices of oil and oil products. The primary motivation for writing this paper was to provide a comprehensive view of the significant role which oil has played, and still plays, in the global economic system. We will also try to quantify the threat posed to the Czech economy by a potential medium-strong oil price shock.

The relationship between monetary policy and oil prices is not a frequently addressed topic in the economic literature, especially that focusing on small open economies. This is especially true as regards analysis of the Czech economy. In this paper we evaluate the sensitivity of a small open economy (Czech economy) and monetary policy to a potential oil price shock.

This paper is structured as follows. Section 2 describes the evolution of oil and oil product prices and their relation to key macroeconomic variables. Section 3 discusses the relationship between monetary policy and oil prices in the context of selecting optimal oil extraction volumes (producers) and corresponding inventory levels (oil refiners) and the effect of financial speculation (investors). Section 4 first defines the optimal central bank response to oil prices, then shows retrospectively which prices have entered the CNB’s forecasting process and provides results of a simulated positive transient and a permanent oil price shock (a rise in the oil price of USD 30/b). Furthermore, we also simulated a transitory and permanent slump in the oil price by 20% from the average level of Brent crude oil price in the third quarter of 2014, i.e. USD 100/b. The final section summarizes and offers recommendations.

2. Key empirical facts

This part demonstrates key empirical facts about oil and oil products, their relationship with other commodity prices and key macroeconomic variables including the USD exchange rate.

2.1 Oil price and key macroeconomic variables

Figure 1a shows the long-term evolution of the nominal and U.S.-CPI deflated real oil price. The real oil price at the time of the first and second oil price shocks was not surpassed until the beginning of 2005. Figure 1b illustrates the generally inverse relationship between the USD real effective exchange rate and the oil price (in USD/b).

Figure 2 illustrate the relationship between oil prices and key macroeconomic variables. Oil prices and CPI inflation\(^3\) in advanced (G7) countries show a clear dependence (Figure 2a) – a change in the oil price passes through to inflation almost immediately. Figure 2b illustrates signs of an inversion relationship between oil prices and economic growth over most of the period under review. This mismatch is partly due to the slower adjustment of oil prices to changes in the phase of the business cycle.

Figure 3 show the relationship between real oil prices and the real interest rate. Its logic is explained by the Hoteling model, in which oil owners decide on the basis of the real interest rate whether to extract oil and sell it or not to extract it and leave it in the ground. If the oil price is rising so fast that oil in the ground guarantees higher yields than the money obtained by selling it, the owners will prefer to leave it in the ground – they will postpone production in an effort to achieve higher prices in future. This reduces current supply and increases current prices while increasing future demand and reducing future prices. In a world of certain

proprietary rights and perfect information this continues until the estimated price of oil adjusted for extraction costs is rising at a rate equal to the market interest rate. If interest rates fall, other things being equal, an impulse to slow down current oil extraction and achieve higher prices will arise. This should generate a negative correlation between interest rates and oil prices. If we put together the rapid demand growth and low real interest rates seen in recent years, then rapid growth in oil prices is a logical result of the Hotelling model.

2.2 Oil price and the USD exchange rate

There is traditionally a negative correlation between the dollar exchange rate and oil prices; although the relationship between the two has undergone major changes in the past (see Figure 4). Breitenfellner and Cuaresma (2008) divide the relationship from 1950 to the present into roughly four periods according to the volatility of, and correlation between, the two variables. These periods coincide with regime shifts in oil and money markets.

The first period (1950–1970) was characterized by low oil price volatility and a strong negative correlation (−0.62). The Bretton Woods system of fixed exchange rates was in place. Other characteristics included low inflation, low interest rates and high economic growth. Oil prices were controlled by seven large international corporations that dominated oil production, refinement and distribution.

The following period between 1971 and 1984 was one of high volatility and the negative correlation was not so strong (−0.18). In August 1971, President Nixon announced the discontinuation of the gold convertibility of the U.S. dollar given a deteriorating U.S. balance of payments. This move resulted in a steep depreciation of the dollar against gold and other world currencies. OPEC, whose purchasing power had decreased, was slow to react to the

4 The different correlation figure (−0.97) from our calculations for the period may be due to the use of different methods for calculating the EUR/USD exchange rate before 1999.
dollar’s depreciation. Only two years later, during the Yom Kippur War (October 1973), OPEC cut its oil production and placed an embargo on oil exports to the West. The price of oil quadrupled in a year, while the dollar continued to depreciate. The next oil crisis started in autumn 1978 in the wake of the Iranian Revolution, which led to a temporary fall in oil production in the country. The subsequent growth in oil prices was boosted by a phased decontrol of oil prices by the Carter administration. The price of oil again quadrupled in a year. At the end of the second period (1981–1984) the dollar regained strength sharply as a result of restrictive Fed monetary policy (under Chairman Paul Volcker) and the price of oil fell slightly despite a decrease in oil supply due to the Iraq–Iran conflict. The strengthening dollar and economic recession in the USA probably played a stronger role.

In the third period (1985–1998) both the dollar exchange rate and the oil price were less volatile. The correlation was no longer negative (+0.44). OPEC lost its power to set prices when Saudi Arabia almost doubled its production in August 1985. This was followed by a fall in oil prices. Throughout the period OPEC was unable to take effective action to raise them. In September 1985, the Plaza Accord was signed in the United States with the aim of devaluing the dollar. This was intended to reduce the current account deficit and help the country emerge from recession. Over the following two years, coordinated central bank intervention caused a depreciation of the dollar by more than 50%. The price of oil surged temporarily in August 1990 as a consequence of the Iraqi occupation of Kuwait but subsequent declined almost uninterruptedly. This is put into context with transition-induced recession in the former Soviet Union and in Central Europe. Oil prices reached their low point as a result of the Asian crisis (1997–1998).

The recent period (since 1999) has been marked by high volatility and a renewed strong negative correlation (−0.80). Owing to low investment in the previous periods, oil producers were unable to keep pace with rising oil consumption due to rapid growth in demand in emerging (Asian) economies. Reserve extraction capacity decreased and oil prices started to rise dramatically. As non-OPEC production was already beyond its peak, the oil cartel’s price-setting power increased. Fundamentals, geopolitical risks and excess liquidity resulting from easy monetary policy caused an inflow of speculative money into the oil market. This, in turn, bolstered the growth in oil prices and caused a speculative bubble to form. This bubble burst in July 2008 and the oil price temporarily collapsed. However, thanks to the renewed market power of OPEC, the price very soon returned to the level which OPEC considers favorable for both oil producers (in terms of investment efficiency) and consumers.
The negative correlation between the USD exchange rate and the oil price for most of this period is no accident and can be attributed to five channels (see Breitenfellner and Cuaresma, 2008): (i) The purchasing power of oil export revenues on the supply side – oil exporters aiming to stabilize the purchasing power of their (U.S. dollar) export revenues in a situation where their imports are mostly paid for in euro. A condition for this channel to function is that oil-exporting countries must – at least partially – have the power to affect oil prices by altering supply. In fact, OPEC’s power was highly volatile in the past, but with soaring demand from China and other emerging economies and with production having peaked in most non-OPEC countries, OPEC’s significance has recently increased considerably. (ii) Local prices in non-dollar regions on the demand side – the dollar’s depreciation reduces oil prices in countries whose currencies have strengthened against the dollar, thereby increasing demand for oil and the oil price denominated in dollars. (iii) Investment in oil-related markets – the dollar’s depreciation reduces foreign investors’ returns on U.S. dollar-denominated financial assets, hence increasing the attractiveness of oil and other commodities as an alternative investment for foreign investors. Investment in commodities is also used by U.S. investors to hedge against domestic inflation, the risk of which increases as the dollar depreciates. (iv) Monetary policy and exchange rate regimes – the dollar’s depreciation entails an easing of monetary policy conditions in countries whose currencies are pegged to the dollar (including oil exporters and China). In turn, demand – including demand for oil products – rises in those countries. In such cases, however, this may involve only an apparent

5 Anchoring oil exporters’ currencies to the U.S. dollar is criticised from the perspective of global trade imbalances (oil exporters’ current account surpluses largely correspond to the U.S. current account deficit). It is not certain, however, that higher consumption in oil-exporting countries would reduce the U.S. deficit, as these countries import primarily from Europe and Asia. By contrast, higher imports could increase oil consumption in Europe, where oil price growth has not been so dramatic in the past.
correlation, with the USD/EUR exchange rate and the price of oil in fact being co-determined by a third variable, namely the real interest rate (if uncovered interest parity applies). (v) Efficient currency markets – currency markets are possibly more efficient than oil markets and hence anticipate developments in the real economy that affect the demand for and supply of oil.

The above-mentioned channels assume that causality goes from the dollar exchange rate to the oil price. This is contradicted by a number of studies which also admit the opposite direction of causality, i.e. from the oil price to the dollar exchange rate, and particularly to the exchange rates of commodity currencies (the currencies of major global commodity-exporting countries). In the empirical part of their study, Breitenfellner and Cuaresma (2008) find that the direction of causality is unclear, but they also come to the relatively strong conclusion that the inclusion of the EUR/USD exchange rate among a model’s explanatory variables improves its ability to predict future oil prices.

3. Links between monetary policy and the price of oil

The accelerating growth in the prices of oil and other commodities which can be observable since 2003 is causing many to ask what is causing this growth. The sustained economic boom in Asia, growing demand in emerging economies, political instability (Venezuela and Nigeria; unrest in the Middle East), gradually depleting reserves of oil (commodities) and rising extraction costs are usually cited as the main reasons. However, this hypothesis is contradicted by developments over the last three years. The world economy started to slide into recession in late 2007. This situation was aggravated by the fall of Lehman Brothers on 15 September 2008 and by the onset of the global financial crisis. Meanwhile however, the price of oil surged by almost 100% starting in late 2007. Almost all mineral and agricultural commodities then recorded rising prices. A strong correction of oil and other commodity prices occurred only in the second half of 2008. Since 2009, commodity prices have been rising sharply again. The question is what is causing these contradictory trends of strongly rising commodity prices and an economy sliding into recession. Are demand and supply factors tied to economic growth a sufficient reason for the surge in commodity prices? If global economic growth since 2002 does not explain this surge, where should we look for its causes?

One group of economists believes that the recent dramatic rise in commodity prices could not have been caused solely by supply and demand for commodities including oil (as assumed by the traditional hypothesis), but that it was due largely to cheap money. A possible thanks to the appreciation of the euro. Further dollar oil price growth would lead, in turn, to a further deterioration in the U.S. current account deficit.

explanation can therefore be found in how monetary policy has been conducted, or rather in the real interest rate level, which is a very important factor underlying real commodity prices.

Figure 5: Real commodity prices at times of high and low real interest rates.

![Figure 5](image_url)

Figure 5 describes the relationship between real (CPI deflated) interest rates in the USA and the Commodity Research Bureau Index in real terms. Commodity prices have been low at times of relatively high interest rates, i.e. tighter Fed monetary policy (shown in blue), and high at times of relatively low rates. This would suggest that interest rates have a greater impact on the prices of oil and other commodities than generally assumed so far.

The current high commodity prices may therefore be a result of the Fed’s long-running easy monetary policy, which started in 2001. A second wave of aggressive cuts started in October 2007. The Fed lowered its key policy rate from 4.75% to only 0.25% at the end of 2008, i.e. over a period of just 14 months. On the one hand, this was a logical consequence of the situation facing the U.S. economy (i.e. the technology bubble, the terrorist attacks of 2001, the economic downturn, etc.). On the other hand the sustained easy monetary policy probably led to overall growth in asset prices, including commodity prices. Figure 6 shows the dynamic growth of real prices of individual commodity categories (i.e. industrial metals and agricultural commodities as well as the overall commodity basket), Brent crude oil prices and U.S. real interest rates. In the period of rising rates (i.e. the 1980s and 1990s), commodity prices did not record such high growth as after 2000, when interest rates were falling sharply. The different trends in the two periods are most visible in prices of agricultural commodities (non-storable, perishable) and mineral commodities (storable), i.e. oil and industrial metals.

---

7 The CBR Index describes the overall direction of commodity prices. It is a measure of the price movements of 19 basic commodities. The greatest weight is assigned to oil (23%), followed by copper, corn, gold, live cattle, soybeans and natural gas (6%), cocoa, coffee, cotton, heating oil, unleaded petrol and sugar (5%) and nickel, orange juice, silver, wheat and pork (1%).

8 The key interest rate was gradually lowered from 6.50% on 3 January 2001 to 1.00% on 25 June 2003.
For example, Frankel (2006) states that the effect of real interest rates on the supply of, and demand for, storable commodities can be transmitted through these channels: (i) production, (ii) inventories and (iii) financial speculation.

3.1 Production

When interest rates are low, producers leave oil in the ground instead of extracting it and storing it in tanks (see the Hotelling model). In this case it is virtually impossible for excess supply of storable commodities (oil, natural gas, metals) to amass. Prices then rise as new oil deliveries fail to keep pace with growth in global demand. This would mean that some cases of apparent stagnation in oil deliveries as a result of low capacity are merely an illusion – oil producers are able to keep up with rising demand, but low interest rates encourage them to keep more unextracted oil in the ground, thereby creating an impression of stagnating oil supply.⁹

3.2 Inventories

Low real interest rates lead to expectations of rising oil prices in the future. That prompts oil producers to increase their oil inventories, as stored oil can be sold at a higher price later on. Hence, the motivation of companies to transport their inventories to the distribution network weakens, while demand for storable commodities increases. Oil inventories are therefore held in tanks and the decision on how much oil to sell involves weighing the interest rate level against expected future growth in prices. If the rate of return on financial assets is extraordinarily low, it is better to keep oil in tanks than to sell it today and reinvest the proceeds.

⁹ This also applies to other storable and non-perishable commodities, i.e. how much copper to mine, how much of a forest to log, etc.
3.3 Financial speculation

Low interest rates encourage speculators to shift their investment interests (capital) out of relatively risk-free short-term interest-bearing financial instruments (e.g. Treasury bills) to very risky commodity contracts, which on the other hand can generate higher returns. Therefore, rational investors (i.e. small investors, banks, pension funds and hedge funds) seeking higher returns in an environment of low interest rates – even if that means taking on a higher degree of risk – are a key factor of speculative growth in commodity prices.

All these three mechanisms can therefore foster growth in real commodity prices. The theoretical model can be summarised as follows: expansionary monetary policy temporarily lowers real interest rates (whether via a fall in nominal rates or a rise in expected inflation). This stimulates growth in commodity prices in real terms. Commodity prices can then rise until they are widely considered overvalued. In that situation, there is a prevailing expectation of a future decline in prices (and other costs, i.e. storage costs, transaction costs, the risk premium, etc.) that is sufficient to offset the low interest rates (and other benefits of carrying inventories – the convenience yield10). If we imagine the logic underlying, for example, the theory of exchange rate overshooting (see Dornbusch, 1976) and we replace the exchange rate with the price of commodities, then in the long run – when the price level adjusts to the change in money supply – the real interest rate and real commodity price should return to their initial levels.

4. Prices of oil in the CNB’S forecasting process

In this section we focused on both the adequate central bank reaction to oil price shocks and the capabilities of the CNB’s forecasting process with regards to anticipating oil price

4.1 How should a central bank react to an oil price shock?

There is a clear consensus across the economic literature that central banks should closely monitor and analyze developments in asset markets (including oil and other commodity markets).11 However, in the case of oil prices (as opposed to, say, stock or property prices), the debate is more or less limited to their impact on the CPI, and especially the extent to which these supply shocks should be exempted. The experience of recent years suggests that making exemptions, or targeting core inflation, may be a mistake, as commodity price growth forms part of the contrary movements in relative prices and moreover reflects monetary policy settings (i.e. it is not a classic exemptible exogenous shock).

Growth in oil prices – or the second-round effects of such growth on inflation – should lead, ceteris paribus, to an increase in the central bank’s rates. It is a negative supply shock. If

10 The benefit or yield associated with physically holding a commodity rather than holding a derivative linked to the commodity.
11 For more details on this debate, see Posen (2006) and Roubini (2006), and for a discussion focusing on transition countries see Frait and Komárek (2007).
demand remained unchanged, inflation would have to rise at least temporarily. There are two fundamental problems here. First, we do not usually know whether the shock is permanent or transitory. Transitory shocks (especially those stemming from global demand) can cause input prices to rise, but their effect on consumer prices (higher prices of fuels, food, etc.) is smaller. If the shock is considered transitory, the central bank’s optimal reaction could be to raise real interest rates slightly in order to moderate demand. If the shock is permanent, it lowers the economy’s potential and, ceteris paribus, real interest rates should also rise. However, if expectations of a permanent decline in productivity reduce permanent income, consumption will fall, followed by investment. Ultimately, even temporarily reducing real interest rates in an effort to prevent an excessive drop in demand may be the optimal monetary policy reaction. The reduction can be temporary because net investment should return to its original level after some time (at a lower absolute level of capital). If we add the intertemporal aspect to the equation, the situation becomes even more complicated. A temporary reduction of real interest rates would shift part of demand from the future to the present, thereby only postponing the problems or requiring an even larger reduction of real interest rates in the future. Overall, it is apparent that the optimal monetary policy reaction to an oil price shock is hard to define within the prevailing theory, partly because a significant part of the shock may be endogenous rather than exogenous.

The second problem is that growth in the prices of oil or other commodities is not an isolated shock, so the ceteris paribus condition does not apply. On the contrary, it takes place amid significant changes in the world economy and, of course, in the Czech economy as well. The latter is undergoing structural changes that are probably raising potential growth. This is an anti-inflationary phenomenon running counter to the effects of rising prices of oil and other commodities. In addition, other significant processes are taking place in the world economy, e.g. a weakening of the U.S. dollar. In small open economies (such as the Czech Republic), this is directly causing a decline in import prices in koruna terms, which has potential first- and second-round effects on inflation. Other important effects also exist. Given the positions of the euro and dollar in Czech exports and imports, the terms of trade will improve, increasing the funds available to the domestic economy. Other effects may ensue from the decline in koruna prices of technology imported from the dollar area. This can be regarded as a positive supply shock, reducing investment costs and increasing the economy’s potential. The depreciation of the dollar should also act indirectly via its potential impacts on European exports. Economists differ significantly in their assessment of the strength of this
effect. Despite all the problems with identifying the optimal monetary policy reaction, we can show how monetary policy responds to oil price shocks in the CNB’s modelling system.\footnote{However, the modelling system largely ignores the long-term impacts of oil price changes on the supply side of the economy; these could be incorporated using expert judgement during the preparation of the real forecast.}

\subsection*{4.2 Oil price outlooks and the forecasting process at the CNB}

Since the July 2006 forecast, the CNB’s forecasting system has been using the price of Brent crude oil, the outlook for which is derived from futures contracts. Brent crude oil replaced the previously used Ural crude oil. The forecast for the price of Ural crude oil was derived from the WTI crude oil price forecast published regularly by the Consensus Forecasts (CF). In addition, since April 2006, the forecasting system has also been using fuel prices, forecasts for which are derived from swap contracts on (ARA: Amsterdam–Rotterdam–Antwerp) exchanges in north-western Europe.

Oil and petrol prices are currently derived from futures contract quotations. These are determined as of the Consensus Forecasts (CF) survey date in order to ensure consistency with the other external indicators. The CF forecast is only available for the three-month and one-year horizons (meaning that developments at other time horizons have to be calculated), whereas futures contract quotations are available several years ahead at monthly frequency. The expected future evolution of oil and petrol prices calculated on the basis of such quotations is therefore better defined. Moreover, a CNB analysis has revealed that since 2004 futures contracts have predicted the future WTI oil price (the only oil price indicator contained in CF) better than the analysts’ estimates contained in the CF survey, especially at the longer horizon. Simulated forecasts of the index of import prices of energy-producing materials based on prices of various types of oil have proved that Brent crude oil has the highest explanatory power. Likewise, petrol prices on the ARA exchanges are the best available indicator for estimating retail fuel prices at filling stations in the Czech Republic.

Figure 7 compares the actual prices of Ural and Brent crude oils in USD/b with the individual forecasts entering the CNB’s forecasting process (thin black lines). As Figure 7 shows, the oil prices entered into the forecasting process were lower than the actual subsequent prices in the vast majority of cases. This confirms the hypothesis that the oil prices gathered in the CF, or stemming from market outlooks, are backward-looking. However, this is linked with the fact that prices were rising significantly over most of the period under review. It can also be seen that, with the exception of the recent past, the outlooks are not good at capturing either the direction of movement or turning points.
4.3 Impact of an oil price shock on the external and domestic economy – rise of oil price by 30 USD/b

The impact of an oil price shock (i.e. a step increase of USD 30/b) was estimated for the Czech economy using a model\textsuperscript{13} (g3) in two basic variants – a transitory one-year increase and a permanent increase. The impact on the euro area economy, which is used here to demonstrate an exogenous environment, was consistently calculated by simulation of the NiGEM model. Tables 1 and 2 contain the expected paths of the exogenous variables, while Figures 8 and 9 show the g3 model outputs in the form of the path of the endogenous variables according to the baseline scenario and the deviation induced by the oil price shock.

4.3.1 Transitory one-year oil price shock (+ USD 30/b)

An oil price increase of USD 30/b was reflected fastest in a rise in external interest rates and a decline in external GDP (see Table 2). Except for a lag in Q1, external PPI inflation also rose simultaneously. The price shock faded fastest in the case of external interest rates, which after rising in response to the price shock fell sharply in 2011 Q1 and continued declining steadily thereafter. The decline in external GDP slowed in the following quarter. The slowest adjustment was observed for PPI inflation, which started to slow in 2011 Q3.

The effects of the transitory one-year oil price shock on the Czech economy are described in Figure 8. A transitory increase in oil prices generates higher inflation pressures (see Figure 8a) via growth in import prices and domestic regulated energy prices. The implied domestic interest rate path (see Figure 8b) is thus shifted slightly upwards in order to counteract the expected inflationary pressures (via a decline in domestic real economic activity). GDP declined slightly (by 0.1 percentage point) in Q2, but returned to its initial level after a year. The largest deviation is observed for the nominal CZK/EUR exchange rate (see Figure 8d). The koruna appreciates strongly against the euro in Q3, owing mainly to growth in external PPI inflation and also to a slight transient rise in external interest rates (which started to fall sharply in 2011 Q1) relative to domestic rates.

### 4.3.2 Permanent oil price shock (+ USD 30/b)

For all the selected exogenous variables, the difference between the permanent and transitory oil price shocks are reflected mainly in a sharp deviation from the baseline scenario in 2010 (see Table 2). The return to the baseline scenario values is then very slow in 2011. The price shock was again reflected fastest in external interest rates and GDP. PPI inflation again responded with a lag of one quarter. The GDP decline started to slow in 2011 Q2. External interest rates also started to fall moderately in this period. The interest rate path changed later than in the case of the one-year price shock, while external interest rates remained relatively high until the end of 2011. As in the previous variant, the price shock...
abates most slowly in the case of external PPI inflation, which does not start to decline until the start of 2011 Q3.

The impact of the permanent oil price shock on the endogenous variables is demonstrated in Figure 9. As regards CPI inflation (see Figure 9a), domestic interest rates (see Figure 9b) and annual real GDP growth (see Figure 9c), the observed variables followed a similar pattern as in the case of the transient shock, the only difference being a stronger and longer-term response this time. The only major change is seen for the nominal CZK/EUR rate (see Figure 9d) – the koruna responds by depreciating for a short time and then converging towards the euro exchange rate. By the end of 2011, the koruna is again appreciating modestly against the euro. This different pattern (the koruna oscillating around the euro exchange rate) compared to the previous variant is due mainly to two contrary factors: higher growth and a gradual decline in external interest rates (depreciation of the koruna) and growth in external PPI inflation, which exerts appreciation pressure on the koruna. In the end, these two effects cancel each other out – the effect of higher external interest rates prevails in the first phase up to the end of 2011 and is subsequently outweighed by the effect of higher external PPI inflation and renewed appreciation of the koruna.

4.4 Impact of an oil price shock on the external and domestic economy – slump in the oil price of 20%

The impact of a slump in oil price (i.e. a step decrease by 20%) was estimated for the Czech economy using a model\(^{14}\) (g3) in two basic variants – a transitory one-year decrease and a permanent decrease. The impact on the euro area economy, which is used here to demonstrate an exogenous environment, was consistently calculated by simulation of the NiGEM model. Tables 3 and 4 contain the expected paths of the exogenous variables, while Figures 10 and 11 show the g3 model outputs in the form of the path of the endogenous variables according to the baseline scenario and the deviation induced by the slump in oil price.

4.4.1 Transitory one-year slump in the oil price (- 20%)  

A slump in the oil price of 20% was reflected in all measured external variables simultaneously in 2014 Q4 (see Table 3). The strongest reaction was observed for PPI inflation, which started to fall very sharply. The price shock faded also in the case of external interest rates, which were lowered in response to the slowdown in prices from their very low initial level to the zero lower bound in 2014 Q4 and stayed there over the entire forecast horizon. The external GDP responded immediately to this positive supply shock by an acceleration in its pace. The effect of a transitory one-year slump in the oil price subsequently faded quickly in the case of external PPI, which returned to positive differences in 2016 Q4.

The effects of the transitory one-year slump in the oil price on the Czech economy\textsuperscript{15} are shown in Figure 10. A transitory decrease in the oil price generated lower inflation pressures at the beginning of the forecast horizon (see Figure 10a) via a decline in import prices and domestic regulated energy prices. During first two quarters the nominal CZK/EUR exchange rate responded by weakening, owing mainly to the decline in external PPI inflation (see Figure 10d). Then the koruna started to strengthen against the euro, when the effects of higher growth in net exports prevailed reflecting increasing foreign demand. The implied domestic interest rate path remained unchanged at ZLB until the end of 2016 Q1 – where the exit from the unconventional monetary policy was planned (see Figure 10b). After this slight increase in interest rates can be observed, in response to increasing domestic inflation pressures from the middle of 2015, reflecting faster growth in domestic real economic activity (see Figure 10c).

\textbf{4.4.2 Permanent slump in the oil price (-20\%)}

For all the selected exogenous variables, the difference between the permanent and transitory oil price shocks is reflected mainly in a sharp deviation from the baseline scenario over the entire forecast horizon (see Table 4). As in the previous temporary one-year oil price shock, all measured external variables reacted immediately in 2014 Q4. The return to the

baseline scenario values was much slower during 2015. The price shock was again reflected mostly in external PPI, which responded by an immediate sharp decline. External interest rates were lowered again simultaneously to the zero lower bound level in response to downside price pressures. Over the same period the external GDP started to increase in response to a slump in the oil price, representing a positive supply shock to the euro area economy. External interest rates remained at the zero lower bound over the entire forecast horizon and longer than in the case of the one-year price shock.

The impact of the permanent slump in the oil price on the endogenous variables is demonstrated in Figure 11. As regards CPI inflation (see Figure 11a), domestic interest rates (see Figure 11b) and annual real GDP growth (see Figure 11c), the observed variables followed a similar pattern as in the case of the transient shock, the only difference being a stronger and longer-term response this time. The only major change is seen in the path of the nominal CZK/EUR rate (see Figure 11d) – the koruna responded by with strong appreciation over the entire forecast horizon, driven by very high foreign demand supporting the growth of domestic net exports. This effect outweighed the pressures of lower external PPI and reduced domestic import and administered prices, which acted on the nominal CZK/EUR rate in the opposite direction.

5. Conclusions

The significant upward tendencies in commodity prices in recent years, which are certainly having a strong effect on price-setting, represent a big challenge for monetary policy. While the traditional economic view says that demand and supply factors are usually the key factors determining changes in prices of oil and other commodities, the effect of monetary policy cannot be disregarded in this respect. The results of our observations show that real commodity prices tend to decline as the interest rate rises and increase as it falls. The Fed’s easy monetary policy over the past 10 years has been an important aspect of the rise in commodity prices, i.e. real interest rates – along with other factors – are important determinants of real commodity prices. Speculative demand supported by low global interest rates artificially pushes prices above the level of classical market prices created by supply (commodity suppliers) and demand (processors). Sustained easy monetary policy in turn causes investors (speculators) to shift to commodities. Over time, and as financial markets develop (are modernised) towards providing a wide range of instruments (especially various types of derivatives linked to underlying assets – commodities), financial flows become more and more sensitive to changes in interest rates. This is why commodity prices have continued to show a sharp upward trend despite the recent global fall in demand. The above arguments therefore favour generally tighter monetary policy. Consequently, central banks should closely monitor commodity prices as an indicator of potential future inflation pressures.

An empirical analysis conducted using the NiGEM model and the CNB’s macroeconomic model (g3) tells a similar story. This analysis consisted in modelling the impacts of a transient and permanent shock to the oil price (an increase of USD 30/b). Macroeconomic variables generally responded more strongly to the permanent price shock in both observed territories. When comparing the two scenarios, the largest change in path was observed for the nominal CZK/EUR exchange rate, which appreciated strongly against the euro in the case of the transitory oil price shock. In the case of the permanent shock, a higher level of, and gradual decline in, external interest rates caused a short-term depreciation of the koruna, which was soon replaced by a slight appreciation due to higher external PPI inflation. An increase in the real GDP growth (y-o-y, in %) and nominal CZK/EUR exchange rate.
oil price of USD 30/b therefore proved non-fatal for both the global and the Czech economy. The contrary oil shock in the form of a temporary and permanent slump in the oil price mainly reflected a positive supply shock resulting in a faster growth in external demand and a decline in foreign prices, stimulating a growth in domestic economic activity and inflationary pressures over the distant forecast horizon. This was also reflected in a stronger koruna, only in the case of a transitory shock, did the effect of a lower external PPI prevail in the short term, but after two quarters the koruna has also begun to strengthen.

As regards the evolution of oil prices going forward, risks can currently be identified mainly in the gradual modest recovery of the world economy and the expected renewed growth in demand. Another potential risk is the excess money that has been pumped into the world economy as part of stimulation measures introduced during the crisis. In the event of a late or insufficient exit from the current expansionary monetary policy, the spare funds (those not corresponding to the needs of the real economy) might be moved into oil and other commodities via purchases of derivatives. In such case, it would not be possible to view the subsequent price growth – exceeding central banks’ inflation targets – as a supply shock. Hence, the absence of a corresponding monetary policy reaction would not be justified, as monetary policy itself would be the originator of a price shock.
